Ch 7. Greek Letters and Trading Strategies

I. Option Greek Letters

II. Numerical Differentiation to Calculate Greek Letters

III. Dynamic (Inverted) Delta Hedge

IV. Selected Trading Strategies

• This chapter introduces the features of the Greek letters of options first. Next, the numerical differentiation methods to calculate Greek letters are discussed. Third, the dynamic delta hedge method, which is most common hedging method for institutional option traders, is introduced. Moreover, the inverted delta hedge method to arbitrage from the undervalued Taiwanese convertible bond is discussed. Finally, several selected trading strategies are introduced.

I. Option Greek Letters

• Consider an asset paying a yield \( q \) and its price process under the risk neutral measure \( Q \) as follows.

\[
dS/S = (r - q)dt + \sigma dZ
\]

• The corresponding Black and Scholes formulae for call and put options on the asset are

\[
c = S e^{-qT} N(d_1) - Ke^{-rT} N(d_2)
\]

\[
p = Ke^{-rT} N(-d_2) - S e^{-qT} N(-d_1)
\]

where

\[
d_1 = \frac{\ln(S/K) + (r - q + \frac{\sigma^2}{2})T}{\sigma \sqrt{T}}
\]

\[
d_2 = \frac{\ln(S/K) + (r - q - \frac{\sigma^2}{2})T}{\sigma \sqrt{T}} = d_1 - \sigma \sqrt{T}
\]
• Delta $\Delta \equiv \frac{\partial c}{\partial S}$
  ○ For calls: $\Delta = e^{-qT}N(d_1)$
  ○ For puts: $\Delta = e^{-qT}[N(d_1) - 1]$

Derivation of $\Delta$ of calls:
First, we can derive
$$\frac{\partial d_1}{\partial S} = \frac{\partial d_2}{\partial S} = \frac{1}{\sigma \sqrt{T}} = \frac{1}{S \sigma \sqrt{T}}$$
Next, we proceed the differentiation with respect to $S$:
$$\frac{\partial c}{\partial S} = e^{-qT}N(d_1) - Ke^{-rT}\phi(d_2)\frac{1}{S \sigma \sqrt{T}},$$
where the sume of the last two terms are
$$Se^{-qT}\phi(d_1)\frac{1}{S \sigma \sqrt{T}} - Ke^{-rT}\phi(d_2)\frac{1}{S \sigma \sqrt{T}}$$
for the numerator
$$e^{-qT}\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} - Ke^{-rT}\frac{1}{\sqrt{2\pi}}e^{-\frac{(d_1-\sigma \sqrt{T})^2}{2}}$$
$$(-\frac{(d_1-\sigma \sqrt{T})^2}{2} = -\frac{d_1^2}{2} + d_1 \sigma \sqrt{T} - \frac{\sigma^2 T}{2})$$
$$= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}(e^{-qT} - \frac{K}{S}e^{-rT+d_1 \sigma \sqrt{T} - \frac{\sigma^2 T}{2}})$$
$$= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}(e^{-qT} - \frac{K}{S}e^{\ln(S/K)-qT})$$
$$= 0$$
$$\Rightarrow \frac{\partial c}{\partial S} = e^{-qT}N(d_1)$$

• $\frac{\partial c}{\partial K} = Se^{-qT}\phi(d_1)\frac{\partial d_1}{\partial K} - e^{-rT}N(d_2) - Ke^{-rT}\phi(d_2)\frac{\partial d_2}{\partial K} = -e^{-rT}N(d_2)$, where $\frac{\partial d_1}{\partial K} = \frac{\partial d_2}{\partial K} = -\frac{1}{K \sigma \sqrt{T}}$.

• Theta $\theta \equiv -\frac{\partial c}{\partial T}$ (measuring the time decay of the option value)
  ○ For calls: $\theta = -\frac{S \phi(d_1) e^{-qT}}{2 \sqrt{T}} + qSN(d_1)e^{-qT} - rKe^{-rT}N(d_2)$
  ○ For puts: $\theta = -\frac{S \phi(d_1) e^{-qT}}{2 \sqrt{T}} - qSN(-d_1)e^{-qT} + rKe^{-rT}N(-d_2)$

• Gamma $\Gamma \equiv \frac{\partial^2 c}{\partial S^2}$
  ○ For calls and puts: $\Gamma = \frac{\phi(d_1)e^{-qT}}{S \sigma \sqrt{T}}$
- Vega $\nu \equiv \frac{\partial c}{\partial \sigma}$
  - For calls and puts: $\nu = S e^{-qT} \sqrt{T} \phi(d_1) = K e^{-rT} \sqrt{T} \Phi(d_2)$

- Rho $\rho \equiv \frac{\partial c}{\partial r}$
  - For calls: $\rho = K T e^{-rT} N(d_2)$
  - For puts: $\rho = -K T e^{-rT} N(-d_2)$

- Characteristics of Greek letters
  - $\Delta$:
    1. For calls, $0 \leq \Delta \leq 1$; for puts $-1 \leq \Delta \leq 0$

**Figure 7-1**

(ii) When the time approaches the maturity $T$,
- $\Delta$(call) is 1 if the call is ITM and is 0 if the call is OTM.
- $\Delta$(put) is $-1$ if the put is ITM and is 0 if the call is OTM.

* The value of $\Delta$ jumps almost between only two extreme values and thus varies discontinuously near maturity when the option is ATM.
○ Φ:
(i) For both calls and puts, the value of Φ, which measures the degree of curvature of the option value respect to \( S \), is the same and always positive.
(ii) Since the value of Φ is positive, it benefits option holders.
(iii) The curve of Φ is similar to the probability density function of normal distributions because there is a term \( \phi(d_1) \) in the formula of Φ on page 7-2.
(iv) The value of Φ attains its extreme when the option is at the money since the values \( \Delta \) vary more intensely with respect to the change of \( S \) when the option is at the money.
(v) The kurtosis of the curve of Φ because higher for shorter time to maturity \( T \). The reason is due to the nearly discontinuous change of \( \Delta \), which implies an extremely high value of Φ, near maturity.

**Figure 7-2**

○ \( \psi \):
(i) For both calls and puts, their values of \( \psi \) are the same and positive, which reflects that the values of options increases due to a higher degree of volatility of the underlying asset price.
(ii) The curve of \( \psi \) is similar to the probability density function of normal distributions because there is a term \( \phi(d_1) \) in the formula of \( \psi \) on page 7-3.
(iii) When the time is close to the maturity date \( T \), \( \psi \) becomes smaller, which is due to that the period of time in which the volatility \( \sigma \) can affect the option value become smaller.

**Figure 7-3**
○ $\rho$:
(i) For calls, $\rho$ is positive to reflect the positive impact of a higher growth rate $r$ on the probability of being ITM.
(ii) For puts, $\rho$ is negative to reflect the negative impact of a higher growth rate $r$ on the probability of being ITM.

Figure 7-4

○ $\theta$:
(i) $\theta$ can measure the speed of the option value decay with the passage of time. It is worth noting that unlike the stochastic $S$, $\sigma$, and $r$, the time is passing continuously and not a risk factor.
(ii) The value of $\theta$ is always negative for both American calls and puts. However, it is not always true for European puts because the dividend distribution could make the value of European put rise to cover the time decay of the put value.

Figure 7-5
(iii) For options that are at the money, the time decay of the option value is fastest (than other moneyness) and thus the corresponding $\theta$ is most negative. See Figure 7-6.

Figure 7-6

- The relationship among $\Delta$, $\Gamma$, and $\theta$:
  Based on the partial differential equation of any derivative $f$, 
  $$\frac{\partial f}{\partial t} + (r - q)S\frac{\partial f}{\partial S} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} = rf,$$
  and the definitions of $\Delta$, $\Gamma$, and $\theta$, we can derive
  $$\theta + (r - q)S\Delta + \frac{1}{2}\sigma^2 S^2 \Gamma = rf.$$ 
  If we know the value of the derivative $f$ and any two values among $\Delta$, $\Gamma$, and $\theta$, then we can solve the value of the unknown Greek letter through the above equation.

Moreover, suppose $f$ represents a delta-neutral portfolio, i.e., its $\Delta$ equals 0. Then the relationship between the $\Gamma$ and $\theta$ of the portfolio $f$ can be expressed as
  $$\theta + \frac{1}{2}\sigma^2 S^2 \Gamma = rf,$$
  which implies that for this delta-neutral portfolio, if the value of $\Gamma$ is high, which is a desired feature for option holders, the speed of time decay is also fast, i.e., the value of $\theta$ is fairly negative and thus the option value declines quickly as time goes on.
II. Numerical Differentiation to Calculate Greek Letters

- One of the advantages of the Black-Scholes model is that the proposed option pricing formula is differentiable, which makes it simple to calculate the Greek letters. However, for other numerical option pricing methods, they need to resort to the numerical differentiation to calculate the Greek letters. It is worth noting that for American options, there is no analytic pricing formula and thus a numerical option pricing method combined with the numerical differentiation should be considered.

- The main idea of the numerical differentiation is to employ the finite difference as the approximation, i.e., if $f$ is the option pricing function of any numerical method, then

$$\frac{\partial f}{\partial S} \approx \frac{f(S+\Delta S) - f(S)}{\Delta S} \quad \text{(forward difference)}$$

$$\approx \frac{f(S) - f(S-\Delta S)}{\Delta S} \quad \text{(backward difference)}$$

$$\approx \frac{f(S+\Delta S) - f(S-\Delta S)}{2\Delta S} \quad \text{(central difference)}$$

* Note that to compute the finite difference, it needs double time of the employed numerical option pricing model.
* In this chapter, we focus on two numerical option pricing models, the CRR binomial tree model and the Monte Carlo simulation.

- Numerical differentiation for the CRR binomial tree model.

⊙ Convergent behavior of the CRR binomial tree model: Given $S = 100$, $K = 100$, $r = 0.05$, $q = 0.02$, $\sigma = 0.5$, and $T = 1$, and the Black-Scholes call value is 20.5465. For the CRR binomial tree model, the examined $n$ ranges from 1 to 200. The differences between the results of the CRR binomial tree model and the Black-Scholes model are shown in Figure 7-7.

**Figure 7-7**

![CRR - BS Graph](image-url)
The reason for the oscillatory convergence behavior:
Suppose that when one of the stock price layers \( S_u^j d^{n-j}, j = 0, 1, ..., n, \) e.g., the layer \( m \) with \( S_u^m d^{n-m} \), is close to or coincides on the strike price \( K \), the error of the CRR binomial tree model is minimized.

Next, when the number of partitions \( n \) increases by 1, which changes the upward and downward multiplying factors \( u \) and \( d \), the layer \( m \) could deviate from the strike price and it is very possible that there is no other layers that are quite close to or coincide on the strike price \( K \). Therefore, the error of the CRR binomial tree model becomes larger.

In conclusion, as any stock price layer approaching and deviating from the strike price with the increase of \( n \), the error of the CRR binomial tree decreases and increases, which causes the oscillatory convergence toward the theoretical value based on the Black-Scholes model.

Based on the same logic mentioned above, given a fixed number of partition \( n \), the choice of the \( \Delta S \) may shifts away the stock price layer that may be originally close to or coincides on the strike price \( K \). (It is also possible to shift a stock price layer to become more close to the strike price.) As a result, the oscillatory convergence affects the accuracy of the numerical differentiation to calculate the \( \Delta \) and \( \Gamma \) of options. See Figure 7-8.
By observing the above figure, we can conclude

(i) The oscillatory convergence causes the numerical differentiation method to over- or underestimated $\Delta$ by turns along the $S$ axis.

(ii) A smaller $\Delta S$ is not necessarily better: The discontinuity of $\Delta$ could hurt the estimation of $\Gamma$ based on the numerical differentiation seriously. Note that the error term $\delta/\Delta S$ increases for a smaller value of $\Delta S$, which generates a counterintuitive result that it is not more accurate if you specify a smaller value of $\Delta S$.

* To remedy the estimation problem of $\Gamma$, a large enough $\Delta S$ should be considered.

If you are fortunate such that $\Delta(S + \Delta S/2)$ and $\Delta(S - \Delta S/2)$ are both over- or underestimated, there is no error term associated with $\delta$.

Even when one of $\Delta(S + \Delta S/2)$ and $\Delta(S - \Delta S/2)$ is overestimated and the other is underestimated, the error term $\delta/\Delta S$ is not significantly because firstly $\Delta S$ is large and secondly the difference of $\Delta(S + \Delta S/2)$ and $\Delta(S - \Delta S/2)$ is large enough to dominate the results of the numerical differentiation method.
Another method to calculate Greek letters based on the CRR binomial tree model:

(i) The above numerical differentiation method is with not only the accuracy problem but also the efficiency problem due to the necessity to employ the binomial tree calculation twice.

(ii) To solve both these problem, another method is proposed based on one-time binomial tree calculation.

(iii) However, this method can estimated only $\Delta$, $\Gamma$, and $\theta$.

**Figure 7-9**

\[
\begin{align*}
\Delta & \approx \frac{f_u - f_d}{S_u - S_d} \\
\Gamma & \approx \frac{f_{uu} - f_{ud}}{(S_{uu} - S_{ud})} - \frac{f_{ud} - f_{dd}}{(S_{ud} - S_{dd})} \\
\theta & \approx \frac{f_{ud} - f}{2(T/n)}
\end{align*}
\]

The problems with this method: The estimations of $\Delta$ and $\Gamma$ are actually $\Delta$ and $\Gamma$ at $T/n$ and $T/2n$, but not today. If $n$ approaches infinity, the errors become negligible.

The extended tree model proposed by Pelsser and Vorst (1994), which is an improvement of the above method. See Figure 7-10.
* The extended tree model is more accurate than the method in Figure 7-9. However, similar to the method in Figure 7-9, The extended tree model is applicable only for $\Delta$, $\Gamma$, and $\theta$.

- Numerical differentiation based on the Monte Carlo Simulation:

  ⊙ For the Monte Carlo simulation, the finite difference method together with the technique of common random variables can be employed to compute Greek letters. However, the huge computational burden of the Monte Carlo simulation deteriorates because the simulation needs to be performed twice in the finite difference method.

  ⊙ Here two one-time simulation methods to compute Greek letters are introduced. These two methods, the pathwise and likelihood methods, are proposed by Broadie and Glasserman (1996). In this section, only the European put is taken as example, and it is straightforward to apply these methods to the European call.
Pathwise method: all parameters affect \( S_T \) and in turn affect the option value, so to calculate \( \partial f / \partial x \) for any parameter \( x \), the calculation of \( \partial f / \partial x \) is considered.

Define \( P = e^{-rT}(K - S_T)\mathbf{1}_{\{K \geq S_T\}} \), and the option value today is \( p = E[P] \).

\[
\begin{align*}
\frac{\partial P}{\partial S_T} &= -e^{-rT}1_{\{K \geq S_T\}} \\
\frac{\partial S_T}{\partial S_0} &= \frac{S_T}{S_0} \quad \text{(because} \quad S_T = S_0 e^{(r-q-\frac{\sigma^2}{2})T + \sigma \sqrt{T} \zeta} \text{)}
\end{align*}
\]

(i) \( \Delta = E[\frac{\partial P}{\partial S_0}] \), where \( \frac{\partial P}{\partial S_0} = -e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{S_0} \).

(Note that to estimate \( \Delta \), we first simulate random samples of \( S_T \) and next approximate \( E[\frac{\partial P}{\partial S_0}] = E[-e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{S_0}] \) with the arithmetic average of \( -e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{S_0} \).

(ii) \( \Gamma = E[(\Delta(S_0 + h) - \Delta(S_0))/h] = E[(-e^{-rT} (\frac{S_T}{S_0}) (1_{\{K \geq S_T(S_0 + h)\}} - 1_{\{K \geq S_T(S_0)\}}))/h] \)

\[
= E[e^{-rT} (\frac{S_T}{S_0}) 1_{\{S_T(S_0 + h) \geq K > S_T(S_0)\}}] / h = E[e^{-rT} (\frac{S_T}{S_0}) G(S_T(S_0 + h)) - G(S_T(S_0))]
\]

(because \( \frac{S_T(S_0 + h)}{S_0 + h} = \frac{S_T(S_0)}{S_0} \), and this ratio is independent of \( S_0 \)

\[h \rightarrow 0, S_T \rightarrow K \]

\[
E[e^{-rT} (\frac{K}{S_0})^2 g(K)],
\]

where \( G = \int dg, g(K) = \frac{1}{K\sigma \sqrt{T}} n(d(K)), \text{ and } d(K) = \frac{\ln(K/S_0) - (r-q-\frac{\sigma^2}{2})T}{\sigma \sqrt{T}}.
\]

(iii) \( \upsilon = E[\frac{\partial P}{\partial \sigma}] \), where \( \frac{\partial P}{\partial \sigma} = \frac{\partial P}{\partial S_T} \cdot \frac{\partial S_T}{\partial \sigma} = e^{-rT} 1_{\{K \geq S_T\}} S_0 e^{(r-q-\frac{\sigma^2}{2})T + \sigma \sqrt{T} \zeta} (-\sigma T + \sqrt{T} \zeta)
\]

\[
= e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{\sigma} [\ln \frac{S_T}{S_0} - (r - q + \frac{1}{2}\sigma^2)T].
\]

(iv) \( \rho = E[\frac{\partial P}{\partial r}] \), where \( \frac{\partial P}{\partial r} = -T e^{-rT} 1_{\{K \geq S_T\}} (K - S_T) - e^{-rT} 1_{\{K \geq S_T\}} \frac{\partial S_T}{\partial r}
\]

\[
= -T e^{-rT} 1_{\{K \geq S_T\}} (K - S_T) - e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{\sigma} T T
\]

\[
= -KT e^{-rT} 1_{\{K \geq S_T\}}.
\]

(v) \( \theta = E[-\frac{\partial P}{\partial T}] \), where \( -\frac{\partial P}{\partial T} = re^{-rT}(K - S_T)1_{\{K \geq S_T\}}
\]

\[
+ e^{-rT} 1_{\{K \geq S_T\}} \frac{S_T}{2T} \ln(\frac{S_T}{S_0}) - (r - q - \frac{1}{2}\sigma^2)T].
\]
Define the option value as \( p = \int_{0}^{\infty} e^{-rT} \max(K - x, 0)g(x)dx \)

\[
\begin{align*}
g(x) &= \frac{1}{x \sigma \sqrt{2\pi}} n(d(x)) \quad (g(S_T) \text{ is the probability density function of } S_T) \\
n(z) &= \frac{1}{\sqrt{2\pi}} e^{-z^2/2} \\
d(x) &= \frac{\ln \frac{z}{S_0} - (r - q - \frac{1}{2}\sigma^2)T}{\sigma \sqrt{T}}
\end{align*}
\]

(i) \( \Delta = \frac{\partial p}{\partial S_0} = \int_{0}^{\infty} e^{-rT} \max(K - x, 0) \frac{\partial g(x)}{\partial S_0} dx \)

\[
= \int_{0}^{\infty} e^{-rT} \max(K - x, 0) \frac{\partial g(x)}{\partial S_0} \frac{1}{g(x)} g(x)dx \\
= E[e^{-rT} \max(K - S_T, 0) \frac{\partial \ln g(S_T)}{\partial S_0}] \\
= \left| \frac{\partial \ln g(x)}{\partial S_0} \right|_{x=S_T} = -d(x) \frac{\partial d(x)}{\partial S_0} \left|_{x=S_T} = \frac{\ln \frac{S_T}{S_0} - (r - q - \frac{1}{2}\sigma^2)T}{\sigma \sqrt{T}} \frac{d(S_T)}{S_0 \sigma \sqrt{T}} \right.
\]

(ii) \( \upsilon = \frac{\partial p}{\partial \sigma} = E[e^{-rT} \max(K - S_T, 0) \frac{\partial \ln g(S_T)}{\partial \sigma}] \)

\[
\left| \frac{\partial \ln g(x)}{\partial \sigma} \right|_{x=S_T} = -\frac{1}{\sigma} - d(S_T) \frac{\partial d(x)}{\partial \sigma} \left|_{x=S_T} \right. \\
= \frac{\ln \frac{S_T}{S_0} + (r - q + \frac{1}{2}\sigma^2)T}{\sigma \sqrt{T}}
\]

(iii) \( \Gamma = \frac{\partial^2 p}{\partial S_0^2} = \int_{0}^{\infty} e^{-rT} \max(K - x, 0) \frac{\partial^2 g(x)}{\partial S_0^2} dx \)

\[
= \int_{0}^{\infty} e^{-rT} \max(K - x, 0) \frac{\partial^2 g(x)}{\partial S_0^2} \frac{1}{g(x)} g(x)dx \\
= E[e^{-rT} \max(K - S_T, 0) \frac{\partial^2 g(S_T)}{\partial S_0^2} \frac{1}{g(S_T)}] \\
\left| \frac{\partial^2 g(x)}{\partial S_0^2} \right|_{x=S_T} = \frac{d(S_T)^2 - d(S_T) \sigma \sqrt{T}}{S_0 \sigma^2 T} \\
\]

(iv) \( \rho = \frac{\partial p}{\partial r} = \int_{0}^{\infty} max(K - x, 0) [-Te^{-rT}g(x) + e^{-rT} \frac{\partial g(x)}{\partial r} \frac{1}{g(x)} g(x)] dx \)

\[
= \int_{0}^{\infty} e^{-rT} \max(K - x, 0) [-T + \frac{\partial g(x)}{\partial r} \frac{1}{g(x)}] g(x)dx \\
= E[e^{-rT} \max(K - S_T, 0) [-T + \frac{\partial g(S_T)}{\partial r} \frac{1}{g(S_T)}]] \\
\left| \frac{\partial g(x)}{\partial r} \right|_{x=S_T} \frac{1}{g(S_T)} |_{x=S_T} = \frac{\partial \ln g(x)}{\partial r} \left|_{x=S_T} = -d(S_T) \frac{\partial d(x)}{\partial r} \right|_{x=S_T} = \frac{d(S_T) \sqrt{T}}{r}
\]
\[ (v) \, \theta = -\frac{\partial P}{\partial T} = \int_{0}^{\infty} \max(K - x, 0) \left[ r e^{-rT} g(x) - e^{-rT} \frac{\partial g(x)}{\partial T} \frac{1}{g(x)} g(x) \right] dx \]

\[ = E\left[ e^{-rT} \max(K - S_T, 0) \left( r - \frac{\partial \ln g(S_T)}{\partial T} \right) \right] \]

\[ = \frac{\frac{\partial \ln g(S_T)}{\partial T}}{2T} - d(S_T) \left. \frac{\partial d(x)}{\partial T} \right|_{x=S_T} \]

\[ \downarrow \]

\[ - \ln \frac{x}{S_0} - (r - q - \frac{\sigma^2}{2}) T \]

\[ \approx \frac{2T}{2\sigma T^\frac{1}{2}} \]

* To estimate each Greek letters, we simulate random sample of $S_T$, and next estimate $E[f(S_T)]$ with the arithmetic average of $f(S_T)$, where $f(S_T)$ could be any target functions in the formulae of different Greek letters.
III. Dynamic (Inverted) Delta Hedge

- Consider an institutional investor to issue a call option contract, in which $S_0 = 49$, $K = 50$, $r = 0.05$, $q = 0$, $\sigma = 0.2$, $T = 0.3846$ (20 weeks), and the underlying assets of this call option contract are 100,000 shares of stock. The Black-Scholes model generates the theoretical value of this call option contract to be $240,000.

⊙ Inspired from the derivation of the partial differentiation equation, longing $\Delta_t$ shares of $S_t$ and shorting one share of $C_t$ can form an instantaneous risk free portfolio, i.e.,

$$\Delta_t S_t - C_t = B_t,$$

where $B_t$ is the balance of borrowing costs and lending interests. Rewrite the above equation to derive

$$C_t = \Delta_t S_t - B_t.$$  

That means dynamically adjusting the position $\Delta_t S_t - B_t$ can replicate $C_t$ for any $t$. More specifically, the trading strategy of this dynamic delta hedge method is as follows.

\[
\begin{align*}
&S_t \uparrow, \Delta_t \uparrow \Rightarrow \text{buying stock shares such that the total position is } 100,000\Delta_t \text{ shares} \\
&S_t \downarrow, \Delta_t \downarrow \Rightarrow \text{selling stock shares such that the total position is } 100,000\Delta_t \text{ shares}
\end{align*}
\]

⊙ At maturity, the cost of the dynamic hedging strategy is $5,263,300, and the institutional investor owns 100,000 shares of stock. On the other hand, the call holder exercise this option to purchase 100,000 shares of stock at $50 \times 100,000$. As a consequence, the net cost of the institutional investor is $263,300, which is close to the call premium $240,000.
At maturity, the cost of the dynamic hedging strategy is $256,600, and the institutional investor does not own any share of stock. On the other hand, the call holder give up his right to exercise this option. As a consequence, $256,600 is the net cost of the institutional investor and is close to the call premium $240,000.

When the frequency of rebalancing increases, the payoff of the dynamic delta hedge is more stable and close to $240,000, which is the theoretical value based on the Black-Scholes model.

In practice, the option issuer sells the option higher than the theoretical value, e.g., $300,000 in the above example. The reasons are as follows.

(i) The option issuer needs some profit to undertake this business.

(ii) Theoretically speaking, the hedging costs can approach the Black-Scholes option value only when the rebalancing frequency approaches infinity, which is impossible in practice.

(iii) The transaction costs in the real world may incur more hedging costs than the theoretical amount.

As a result, it is common for option issuers to mark up the option premium. The general rule to decide the option premium is to use a volatility value that is higher than the estimated one by 20%.

Analysis of the hedging cost in different patterns of price movements:

(i) Stock price rises continuously: Purchase $\Delta_0 S_0$ initially, and continue to buy stock shares until $T$. The net payoff of the dynamic delta hedge depends on the relative levels of the average purchasing price and the strike price, which is the selling price of stock shares for the option issuer at maturity.

Figure 7-11

(ii) Stock price declines continuously: Purchase $\Delta_0 S_0$ initially, and continue to sell those purchased stock shares until $T$. Since the purchasing price is higher than the selling price, the hedging cost accumulates continuously.

Figure 7-12
(iii) Normal pattern of the stock price movement: Purchase $\Delta_0 S_0$ initially, continue to purchase stock shares until $S_t$ rises to reach $S_1$, sell stock shares until $S_t$ declines to reach $S_2$, and so forth. It is apparent that some hedging costs occur in the $S_0 \rightarrow S_1 \rightarrow S_2$ round trip due to the trading strategy of purchasing at high and selling at low.

Hence, we can infer that if the stock price movement upward and downward by turns, these price fluctuations (or said price volatility) incur hedging costs.

**Figure 7-13**

![Graph showing the movement of $S_t$ over time with points $S_0$, $S_1$, and $S_2$ marked, and arrows indicating buy and sell shares at these points.]

* If the time period is long enough and the price volatility is also high, then the hedging costs due to the price volatility will dominate the total hedging costs.
Inverted delta hedging strategy: if you can find a relatively cheaper call option in the market, e.g., the call option sold at 200,000 in the above example, then you can reverse your trading strategy to exploit this opportunity. That is, \((-1) \times [C_t = \Delta_t S_t - B_t]\), which is the trading strategy of the dynamic delta hedge, generate the trading strategy of the inverted delta hedge \(-\Delta_t S_t + B_t\), which can replicate the position of \(-C_t\). Since you can purchase a cheaper \(C_t\) and exploit \(-\Delta_t S_t + B_t\) to generate the Black-Scholes option value, you can arbitrage from this opportunity almost certainly.

(Note that in the dynamic delta hedge, the trading strategy incurs some hedging costs. On the other hand, in the inverted delta hedge, its trading strategy generates some trading profits, i.e., the strategy \(-\Delta_t S_t + B_t = -C_t\) can generates the payoff equal to the amount of selling a call option at the theoretical Black-Scholes option value.)

The trading strategy of this inverted delta hedging method is as follows.

\[
\begin{align*}
S_t \uparrow, \Delta_t \uparrow & \Rightarrow \text{selling stock shares such that the total position is } -100,000\Delta_t \text{ shares} \\
S_t \downarrow, \Delta_t \downarrow & \Rightarrow \text{purchasing stock shares such that the total position is } -100,000\Delta_t \text{ shares}
\end{align*}
\]

The result of the above trading strategy:

(i) Short sell \(\Delta_0 S_0\) shares of stock initially and deposit the selling proceed in the bank to earn the risk free rate

\[
\begin{align*}
S_t \uparrow, \Delta_t \uparrow & \Rightarrow \text{Sell more shares at } S_t, \text{and deposit more money in the bank} \\
S_t \downarrow, \Delta_t \downarrow & \Rightarrow \text{Withdraw money from the bank, and use it to purchase stock shares at } S_t
\end{align*}
\]

\Rightarrow \text{The investor accumulates profits by continuously selling at high and buying back at low.}

* If the price moves upward and downward for many rounds and thus the volatility is high, the cumulative profits increase.

* If the price volatility is higher than the estimated one used in the Black-Scholes model, the investor adopting the inverted delta hedging strategy can earn the payoff in excess of the Black-Scholes option value.

If \(S_T \geq K\) \Rightarrow \text{the final position at maturity is to short sell 100,000 shares} \\
\Rightarrow \text{purchase 100,000 shares at } K, \text{ and return these shares} \\
\Rightarrow \text{the remaining balance in the bank account is what you can earn}

(iii)

If \(S_T < K\) \Rightarrow \text{all short selling shares are purchased back before maturity} \\
\Rightarrow \text{the remaining balance in the bank account is what you can earn}

In Taiwan, the convertible bond (CB) can be regarded as a source of cheaper call options. Longing CBs and performing the inverted delta hedge can achieve the above arbitrage strategy.
IV. Selected Trading Strategies

- Interval trading (區間操作): purchase and sell shares proportionately when the stock price falls and rises in the pre-specified price interval.

<table>
<thead>
<tr>
<th>Stock price</th>
<th>Holding shares</th>
</tr>
</thead>
<tbody>
<tr>
<td>70</td>
<td>0</td>

<td>150</td>
</tr>
<tr>
<td>35</td>
<td>175</td>
</tr>
<tr>
<td>30</td>
<td>200</td>
</tr>
</tbody>
</table>

Accumulate profits through continuously performing the strategy of buying at low and selling as high.

If the stock price movements break the interval, the trading strategy pauses until the stock price moves back into the interval.

- Butterfly (蝶狀價差) strategy: Buy one share of call($K_1$) and one share of call($K_3$) and sell two shares of call($K_2$), where $K_2$ is the middle point of $K_1$ and $K_3$. It is also possible to employ put options to construct the butterfly strategy. If the net payoff after the deduction of the transaction costs is always positive regardless of the stock price, the butterfly strategy can result in an arbitrage opportunity.

Figure 7-14

* When the option markets become more efficient, it is rarer to find this arbitrage opportunity.

* An asymmetric butterfly strategy is proposed as follow. For example, if $K_1 = 5800$, $K_2 = 6000$, $K_3 = 6100$, an asymmetric butterfly can be formed through buying one share of call($K_1 = 5800$) and two shares of call($K_3 = 6100$) and selling 3 shares of call($K_2 = 6000$).
• Straddle (跨式部位) and Strangle (勒式部位)

○ Long (short) straddle is an investment strategy involving the purchase (sale) of each share of the call and put option with the same strike price and time to maturity. The chosen strike price is usually close to the current stock price.

**Figure 7-15**

* Long straddle makes profits if the stock price deviates from the strike price moderately. On the contrary, short straddle makes profits if the stock price fluctuation is not far from the strike price.

* Institutional investors use the trading strategy of long straddle frequently.

○ Long (short) strangle is an investment strategy involving the purchase (sale) of each share of the call and put option with the same time to maturity but different strike prices. Note that the strike price of the call is higher than the strike price of the put, and it is usual that the current stock price is between this two strike prices.

**Figure 7-16**

* Long strangle makes profits if the stock price deviates from the strike price extremely. On the contrary, short strangle makes profits if the stock price fluctuation is roughly between the two strike prices of the call and put options.

* Institutional investors use the trading strategy of short strangle a lot.
Arbitrage between American deposit receipt (ADR) and the stock share in Taiwan

⊙ Taking the ADR of TSMC as example: Suppose one shares of ADR of TSMC can exchange for 5 stock shares of TSMC, and one share of ADR is worth US$8, one share of stock of TSMC is worth NT$40, and the exchange rate is US$1 = NT$30.

⊙ Therefore, the current premium ratio equals \( \frac{240 - 200}{200} = 0.25 = 25\% \).

⊙ The intuition behind this strategy:
  · If the premium ratio is high, the price of ADR compared with the share price of TSMC is relatively high, and thus longing undervalued TSMC shares and shorting overvalued ADR is profitable if the premium ratio moves back to the normal level.
  · If the premium ratio is low, the price of ADR compared with the share price of TSMC is relatively low, and thus shorting overvalued TSMC and longing undervalued ADR is profitable if the premium ratio moves back to the normal level.

⊙ The detailed trading strategy is as follows.

(i) Estimated the long term average of the premium ratio, which is assumed to be 20%.

(ii) Define the upper and lower bounds of the premium ratio. In the following figure, the upper and lower bounds are assumed to be 25% and 15%, respectively.

(iii) \[\begin{align*}
\text{If the premium ratio penetrates 25\% from below,} & \quad \text{buy 5 shares of TSMC and sell 1 share of ADR, and the position is closed when the premium ratio moves back to 20\%.} \\
\text{If the premium ratio penetrates 15\% from above,} & \quad \text{short 5 shares of TSMC and buy 1 share of ADR, and the position is closed when the premium ratio moves back to 20\%.}
\end{align*}\]

Figure 7-17

Long term average of the premium ratio of the price of ADR over the share price of TSMC in Taiwan

7-22
The tradoff to decide the upper and lower bounds of the premium ratio.
  • If the band between the upper and lower bounds is too wide, then the frequency to undertake the strategy is too few and thus less profits are earned.
  • If the band is too narrow, then it is difficult to cover the transaction costs.

The main concern of this strategy is the reliability of the estimation of the long term average premium ratio. If the estimation is wrong, it is possible to suffer a lot of losses based on this strategy.

This strategy is preferred by some foreign financial institutions in Taiwan when the market is predictable in a near future.
